ABSTRACT

We present simple stellar population (SSP) models with scaled-solar and α-element enhanced abundances. The SSP models are based on the Dartmouth Stellar Evolution Database, our library of synthetic stellar spectra, and a realistic treatment of horizontal-branch (HB) morphology. In order to test the relative importance of a variety of SSP model ingredients, we compare our SSP models with integrated spectra of 41 Milky Way Globular Clusters (MWGCs) from Schiavon et al. (2005). Using the Mg $b$ and Ca4227 indices, we confirm that Mg and Ca are enhanced by about $+0.4$ and $+0.2$ dex, respectively, in agreement with results from high resolution spectra of individuals stars in MWGCs. Balmer lines, particularly H$\gamma$ and H$\delta$, are reproduced by our α-enhanced SSP models not only because of the combination of isochrone and spectral effects but also because of our realistic HB treatment. Moreover, it is shown that the Mg abundance significantly influences Balmer and iron line indices. Finally, the investigation of power-law initial mass function (IMF) variations suggests that an IMF much shallower than Salpeter is unrealistic because the Balmer lines are too strong on the metal-poor side to be compatible with observations.

Subject headings: stars: abundances — stars: evolution — stars: horizontal-branch — globular clusters: general
1. Introduction

Understanding the star formation and chemical enrichment histories of galaxies from their integrated spectrophotometries is one of the overarching goals of modern astronomy and astrophysics. Over the last two decades, we have learned that massive elliptical galaxies have enhanced \( \alpha \)-element abundances, such as Mg, compared to the Sun (Worthey et al. 1994; Worthey 1998; Lee & Worthey 2005). According to \( \Lambda \)CDM cosmology, it is usually suggested that star formation was most intense at the deep potentials inhabited by massive ellipticals. Their intense star formation skewed the chemical abundance pattern toward the yields from massive core-collapse supernovae.

Central to this line of investigation, the Lick/IDS spectral indices have been widely used to derive the mean age and metallicity of stellar systems such as star clusters and galaxies. It is therefore essential to validate the simple stellar population (SSP; single age and single metallicity) models by comparing conclusions derived from theoretical integrated Lick spectral indices with results obtained from resolved stellar population studies. The most suitable nearby sample is arguably the Milky Way globular clusters (MWGCs). They are generally old, span a broad range of metallicity, and show some \( \alpha \)-element enhancement.

There have been many efforts in the literature to understand the integrated spectroscopic properties of MWGCs (e.g., Burstein et al. 1984; Gibson et al. 1999; Vazdekis et al. 2001; Lee, Yoon, & Lee 2000; Schiavon et al. 2002; Thomas et al. 2003; Lee & Worthey 2005). Although there is mounting evidence that the MWGCs are perhaps not an ideal representatives of SSPs (e.g., Piotto 2009; Yi 2009), they are still very useful targets for the purpose of testing SSP models.

In order to compute the theoretical integrated Lick/IDS spectral indices from SSP models for the broad range of age and metallicity, three components are generally used. They are (1) stellar isochrones and/or evolutionary tracks, (2) stellar spectra, and (3) empirically derived Lick spectral index fitting functions. The fitting functions of Worthey et al. (1994) have been built upon the Lick stellar library that basically follows the galactic chemical enrichment histories throughout the broad metallicity coverage. In a nutshell, stars on the metal-poor side \([\text{Fe/H}] \leq -1.0\) are generally \( \alpha \)-element enhanced, \([\alpha/\text{Fe}] \sim +0.4\) dex and near solar metallicity they are solar-scaled, i.e., \([\alpha/\text{Fe}] = 0.0\).

Stellar evolutionary models and high resolution synthetic spectral libraries have been updated frequently. Some recent examples of \( \alpha \)-element enhanced stellar models are Kim et

\footnote{Worthey & Ottaviani (1997) for H\(\delta\)\(_A\), H\(\gamma\)\(_A\), H\(\delta\)\(_F\), H\(\gamma\)\(_F\). There are different sets of fitting functions in the literature (e.g., Schiavon 2007).}
al. (2002), Pietrinferni et al. (2006), VandenBerg et al. (2006), and Dotter et al. (2007b). In this work, we present scaled-solar and α-element enhanced SSP models for a broad range of age and metallicity that employ the Dotter et al. (2007b) stellar evolution models and the Lee et al. (2009) high resolution synthetic stellar spectra. Realistic horizontal-branch (HB) morphologies are incorporated in order to faithfully represent the MWGCs. Lee et al. (2000) investigated the effects from HB stars with a detailed variation of HB morphologies as a function of age and metallicity. Their input ingredients were, however, the amalgamation of the Revised Yale isochrones with Yi et al. (1997) HB evolutionary tracks. In this work, our HB morphology treatment is based on the recent study by Dotter (2008). This work differs from recent efforts by Coelho et al. (2007) and Schiavon (2007) in that we cover a broader range of metallicity and age and adopt different isochrones, stellar spectra, and realistic treatment of HB morphology.

Milky Way globular clusters are known for their different degree of α-element enhancement from scaled-solar chemical abundances (e.g., Pritzl, Venn, & Irwin 2005). Thus it is important to self-consistently include these abundances patterns at every stage of SSP model construction. We examine our new models with the large, homogeneous dataset of MWGC integrated spectra compiled by Schiavon et al. (2005; hereafter S05). Earlier observational efforts in this category include Burstein et al. (1984), Cohen et al. (1998), and Puzia et al. (2002). However, the S05 dataset is the largest and most representative of the MWGC population.

In the following section, we describe our new models in detail. The results from our models are depicted in § 3. Our models are compared with Lick indices measured from the S05 data in § 4. Section 5 summarizes and concludes this work.

2. Models

The present models are direct descendents of an evolutionary population synthesis code that was developed to study the stellar populations of globular clusters and galaxies (Lee, Yoon, & Lee 2000; Lee, Lee, & Gibson 2002; Lee et al. 2004; Lee & Worthey 2005; Lee et al. 2009). In this work, we take advantage of the recent emergence of isochrones and HB evolutionary tracks with α-element enhancement at fixed [Fe/H] from (Dotter et al. 2007b) accompanied with Lee et al. (2009) high resolution synthetic spectra. We describe how we generate realistic HB morphologies in section 2.2. The standard Salpeter (1955)

---

2 Coelho et al. (2007)’s [Fe/H] range is only from −0.5 to +0.2 and that of Schiavon (2007) is from −1.3 to +0.3. Schiavon (2007) focused only for the blue side of the spectra, so he did not cover Fe5406 index.
initial mass function (IMF) was employed for calculating the relative number of stars along the isochrones. The variation of IMF is, however, investigated and depicted in section 2.3. The investigated ages are 8, 11, and 14 Gyr and the metallicities cover $-2.5 \leq [\text{Fe/H}] \leq +0.0$ with $[\alpha/\text{Fe}] = 0.0$ and +0.4.

We defer the detailed studies on the effects of multiple populations (Piotto 2009), He-enhancement (Yi 2009), CNONa chemical inhomogeneity (Pietrinferni et al. 2009), blue stragglers (Cenarro et al. 2008), and binary stars in GCs to future work.

### 2.1. $\alpha$-Element Enhancement

In this study, we are illuminating the differences between scaled-solar and +0.4 dex $\alpha$-element enhancement at fixed [Fe/H] in the SSP models by varying (1) isochrones alone, (2) synthetic spectra alone, and (3) both isochrones and spectra.

#### 2.1.1. $\alpha$-enhanced isochrones

The stellar evolution models that we employ were described by Dotter et al. (2007b) and we refer the reader to that paper for complete details. We have used their stellar evolution models at $[\text{Fe/H}] = -2.5, -2.0, -1.5, -1.0, -0.5,$ and 0 with $[\alpha/\text{Fe}] = 0.0$ and +0.4 and ages from 2 to 14 Gyr. These are complemented by a self-consistent set of He-burning tracks that extend from the zero-age HB to the onset of thermal pulsations on the asymptotic giant branch. In the models, $\alpha$-enhancement refers to enhancements in the $\alpha$-capture elements $\text{O, Ne, Mg, Si, S, Ca, and Ti}$ by the same amount as specified in $[\alpha/\text{Fe}]$. The models assume that the initial He mass fraction follows $Y = 0.245 + 1.54Z$, where $Y = 0.245$ is the primordial He abundance from big bang nucleosynthesis (Spergel et al. 2003) and the required initial He abundance of the calibrated solar model is $Y = 0.274$.

It must be emphasized that our $\alpha$-enhanced stellar models in this work are set at fixed [Fe/H], rather than fixed metal mass fraction $Z$, so the $\alpha$-elements add additional metals and make the isochrones cooler in general. In this setting, the temperature differences are more significant on the metal-rich side than on the metal-poor as illustrated in Figure 1. The scaled-solar and +0.4 dex $\alpha$-enhanced stellar models of Dotter et al. (2007b) are contrasted in the H-R diagrams at 2, 5, 8, 11, and 14 Gyr in Figure 1. The left panel shows the $\alpha$-element enhancement at $[\text{Fe/H}] = -2.0$, while the right panel displays that at $[\text{Fe/H}] = 0.0$. The 0.4 dex $\alpha$-enhanced isochrones at fixed [Fe/H] are generally cooler than that of the solar-scaled ones and the effects are more significant on the metal-rich side.
2.1.2. α-enhanced synthetic spectra

Investigations into the effects of individual elements on stellar spectra, with the intent of applying the results to galaxy spectra, include such works as Tripicco & Bell (1995) and Korn et al. (2005), who gauged the effects of ten individual elements on the Lick system of 25 pseudo-equivalent width indices introduced by Worthey et al. (1994; Worthey & Ottaviani 1997). In order to investigate the effects of α-element enhancement on the Lick/IDS indices at solar and super-solar metallicity, Lee & Worthey (2005) employed the updated response functions by Houdashelt et al. (2002), which expanded the earlier work of Tripicco & Bell (1995) regarding the sensitivity of each Lick spectral indices as the abundances of individual chemical elements are varied.

The newly compiled synthetic spectra that we employ in this study were described in Lee et al. (2009) and we refer the reader to that paper for details. As noted in Lee et al. (2009), the synthetic spectra are not very accurate in absolute predictions (c.f. Korn et al. 2005; Serven, Worthey, & Briley 2005) hence we employ a differential approach in which the fitting functions of Worthey et al. (1994) and Worthey & Ottaviani (1997) are used as the zero point, and delta-index information as a function of element ratio is incorporated via measuring the synthetic spectral library. This procedure is similar to that of previous investigations (e.g., Trager et al. 2000a,b; Proctor & Sanson 2002; Thomas et al. 2003; Lee & Worthey 2005; Schiavon 2007) but more sophisticated since an entire grid of delta-index information was used as opposed to 2 or 3 synthetic stars at solar abundance as in previous works.

The Lick stellar library generally follows the galactic chemical enrichment, i.e., $[\alpha/Fe] = +0.4$ for $[Fe/H] \leq -1.0$, $[\alpha/Fe] = +0.2$ for $[Fe/H] = -0.5$, and $[\alpha/Fe] = 0.0$ for $[Fe/H] = 0.0$ (e.g., Reddy et al. 2006). In order to compensate for this intrinsic abundance trend rooted in the stellar library, we have employed the synthetic spectra of $[\alpha/Fe] = -0.4$ for $[Fe/H] \leq -1.0$, that of $[\alpha/Fe] = -0.2$ for $[Fe/H] = -0.5$, and that of $[\alpha/Fe] = 0.0$ for $[Fe/H] = 0.0$ for our solar-scaled SSP models. Then for our 0.4 dex α-enhanced SSP models, we have used the synthetic spectra of $[\alpha/Fe] = 0.0$ for $[Fe/H] \leq -1.0$, that of $[\alpha/Fe] = +0.2$ for $[Fe/H] = -0.5$, and that of $[\alpha/Fe] = +0.4$ for $[Fe/H] = 0.0$.

2.2. Horizontal-Branch Morphologies

Following our earlier work (Lee et al. 2000, 2002, 2004; Lee & Worthey 2005), we fully account for the detailed systematic variation of HB morphology with age and metallicity. In Lee et al. (2000) and Lee et al. (2002), we basically followed the Reimers massloss formula
which led to a variation in mass loss with age and metallicity. In this work, we have instead employed the Dotter (2008) mass loss scheme to represent the MWGC HB morphologies. We have adopted a mass loss of 0.16 $M_\odot$ for $[\text{Fe/H}] = -1.5, -1.0, -0.5,$ and 0.0; 0.08 $M_\odot$ for $[\text{Fe/H}] = -2.0$; and 0.015 $M_\odot$ for $[\text{Fe/H}] = -2.5$ from Figure 3 of Dotter (2008). 0.02 $M_\odot$ is used for the mass dispersion. It is important to recognize that Dotter (2008) was focused on a set of similarly old age GCs in that paper so that there was no claim of an age dependence on mass loss. Nevertheless, this trend should be fine so long as it is applied to old GCs. Examples of HB morphologies in the H-R diagram are shown in Figure 1 at $[\text{Fe/H}] = -2.0$ (left panel) and 0.0 (right panel) for 11 Gyr. The small squares are HB stars for the solar-scaled models, while the crosses are the +0.4 dex $\alpha$-enhanced models. Similar to the isochrones, the $\alpha$-enhanced HB stars at fixed $[\text{Fe/H}]$ are also generally cooler than their solar-scaled counterparts.

The number of HB stars are estimated from the number for stars that evolved off the RGB using the Salpeter (1955) IMF. We find that our $R$-parameter values (i.e., the number of HB stars over the number of RGB stars at the zero-age HB stars) are similar to Salaris et al. (2004). Besides the number of HB stars, there are several parameters that can vary the HB morphologies at given age and metallicity such as different mass dispersion, different He, different mass loss. Observationally, indeed, there are variations of HB morphologies at given $[\text{Fe/H}]$ within the GC population. We assign, however, a single HB morphology at a given age and metallicity by delegating a mass dispersion, and a mass loss as described above. The purpose of this study is not to investigate the detailed match between our SSP models and the observations of every single GC, but rather to examine the overall match for the entire range of metallicity.

2.3. IMF Variations

For the calculation of the relative number of stars along the isochrones, we have adopted the standard Salpeter (1955) power-law IMF, where the number of stars ($dN$) in mass interval ($dm$) is described by

$$dN \propto m^{-\chi}dm,$$

with $\chi = 2.35$ in this study. However, we have also investigated the variation of IMF as depicted in the below. The above simple power-law IMF with $\chi = 2.35$ has been varied with exponents of $\chi = 3.35$ (dwarf star-dominant = bottom-heavy IMF) and 1.35 (giant star-dominant = top-heavy IMF). We find that the $\chi = 3.35$ case decreases the RGB number density down to 20%, and the $\chi = 1.35$ case increases the RGB number density up to 375%, relative to that of the standard Salpeter IMF with $\chi = 2.35$. As the HB star number density
scales with the RGB stars, it is seen in the bottom right panels of Figures 2 – 12 that the HB effect becomes significantly more important for the top-heavy IMF.

3. Differential Model Comparisons

Having depicted the theoretical aspects of generating the scaled-solar and $\alpha$-enhanced Lick spectral indices in §2, we now present the results of our SSP models. The effects due to $\alpha$-element enhancement in the isochrones and spectra, HB stars, and IMF variation on several Lick indices are demonstrated in Figures 2 – 12. The figures are organized as follows: In the top left panel, the differences between scaled-solar and $\alpha$-enhanced models (both isochrones and spectra are enhanced) without HB stars (aa-woHB – ss-woHB) are displayed. The top right panel shows the effect of HB stars on the $\alpha$-enhanced models (aa-wHB – aa-woHB). The middle left panels display isochrone effects alone without HB stars (as-woHB – ss-woHB), while the middle right panels show spectral effects alone without HB stars (sa-woHB – ss-woHB). Thus, the top left panels illustrates the combination of the middle panels. The bottom panels depict the variation of IMF effect (the exponent, $\chi$ of the power-law IMF in equation (1) between 1.35 and 3.35) without (bottom left panels) and with HB stars (bottom right panels) at 11 Gyr for our 0.4 dex $\alpha$-enhanced models.

Table 1 lists the spectral effects of 0.4 dex enhancements of individual $\alpha$-elements as well as that of whole $\alpha$-element at 11 Gyr, without the consideration of HB stars, at [Fe/H] = −1.0 and 0.0 for our investigated Lick indices.

3.1. Mg $b$ and Ca4227

Mg $b$:

The top left panel of Figure 2 shows that Mg $b$ becomes significantly stronger with $\alpha$-element enhancement as a function of metallicity. It is demonstrated in the middle panels of Figure 2 that both $\alpha$-enhanced isochrones and spectra make Mg $b$ stronger as a function of [Fe/H], but the latter effects dominates. The top panels show that HB stars do not influence Mg $b$ very much compared to $\alpha$-element enhancement and, in fact, make Mg $b$ slightly weaker. The bottom left panel of Figure 2 shows that Mg $b$ increases about 0.2 Å with a bottom-heavy IMF and decreases about 0.1 Å with a top-heavy IMF; the bottom right panels shows that the IMF effect is slightly reduced if HB stars are included. It is understood that low-mass main sequence stars make Mg $b$ strong.

Ca4227:
Similar to Mg\(b\), it is shown in the middle panels of Figure 3 that both\(\alpha\)-enhanced isochrones and spectra make Ca4227 stronger as a function of \([\text{Fe/H}]\) but, as with Mg\(b\), the latter effect dominates. Also the top panels display that HB stars do not affect Ca4227 much compared to abundance effects in the models, as with Mg\(b\). The bottom panels show that IMF effect is not very significant though the top-heavy IMF becomes noticeable because of the enhanced effect of HB stars.

Table 1 indicates that Mg\(b\) and Ca4227 are predominantly affected by Mg and Ca among\(\alpha\) elements, respectively. At \([\text{Fe/H}] = 0.0\), Ca4227 is also sensitive to oxygen though only about 25\% of the effect is due to calcium.

3.2. Balmer Line Indices

H\(\beta\):

It can be seen in the top right panel of Figure 4 that H\(\beta\) increases as much as 0.7 Å on the metal-poor side (\([\text{Fe/H}] < -1.0\)) for old stellar populations due to blue HB stars. Also, it is noted from the middle panels of Figure 4 that the\(\alpha\)-element effects come mostly from the cooler isochrones, which weaken the temperature sensitive H\(\beta\). The spectral effects are almost negligible, except at solar metallicity. According to Table 1, it is Mg that dilutes the H\(\beta\) at solar metallicity. The bottom left panel displays that H\(\beta\) increases with a bottom-heavy IMF on the metal-rich side (\([\text{Fe/H}] \geq -1.0\)), but the bottom right panel shows that the effect of HB stars become considerably more important with a top-heavy IMF, particularly on the metal-poor side (\([\text{Fe/H}] < -1.0\)).

H\(\gamma\), H\(\delta\):

Similar to H\(\beta\), the top right panels of Figures 5 and 6 show that H\(\gamma_A\) and H\(\gamma_F\) increase as much as 2.4 Å and 1.4 Å, respectively on the metal-poor side (\([\text{Fe/H}] < -1.0\)) for old stellar populations due to blue HB stars. Also, it is noted from the middle panels of Figures 5 and 6 that the isochrone and spectral effects due to\(\alpha\)-element are opposite. According to Table 1, H\(\gamma\) becomes stronger with Mg-, O-, and Si-enhancement, while it becomes weaker with Ti-enhancement. The spectral effects are much less significant for H\(\gamma_F\) than for H\(\gamma_A\) as noted in Lee et al. (2009).

Similar to H\(\gamma_A\) and H\(\gamma_F\), the top right panels of Figures 7 and 8 show that H\(\delta_A\) and H\(\delta_F\) increase as much as 1.8 Å and 1.2 Å, respectively on the metal-poor side (\([\text{Fe/H}] < -1.0\)) for old stellar populations due to blue HB stars. Also, it is seen from the middle panels of Figures 7 and 8 that the isochrone and spectral effects due to\(\alpha\)-enhancement are opposite,
similar to H$\gamma$. According to Table 1, H$\delta_A$ becomes stronger with Mg-, Si-, Ca-, and O-enhancement, while becomes weaker with Ti-enhancement. On the contrary, H$\delta_F$ becomes stronger with Si-, Ca-, and Mg-enhancement, while becomes weaker with Ti-enhancement. It is noted from Table 1 that the effect of O-enhancement is minimal in H$\delta_F$ among H$\gamma$ and H$\delta$ indices. Furthermore, the effect of Mg-enhancement on H$\delta_F$ considerably attenuates compared to that on H$\delta_A$.

The IMF effect in the bottom panels of Figures 5 – 8 is similar to what we denoted in Figure 4 for H$\beta$. The top-heavy IMF makes both H$\gamma$ and H$\delta$ considerably stronger on the metal-poor side ([Fe/H] < −1.0) mostly because of the enhanced effect of HB stars. Without the consideration of HB stars, the bottom left panel of Figure 8 displays that the IMF effect on H$\delta_F$ is minimal among Balmer lines.

### 3.3. Iron Line Indices

Fe5270, Fe5335, Fe5406, Fe4383*3

The top left panel of Figure 9 displays that Fe5270 becomes stronger with $\alpha$-element enhancement except at the solar metallicity. The middle panels of Figure 9 illustrate that, while the cooler $\alpha$-enhanced isochrones at fixed [Fe/H] make Fe5270 stronger at all metallicity, the spectral effect makes Fe5270 weaker on the metal-rich side. According to Table 1, Ca-enhancement makes Fe5270 stronger on the metal-poor side but it is Mg-enhancement which overwhems Ca-enhancement and makes Fe5270 weaker on the metal-rich side. The top right panel of Figure 9 shows that Fe5270 also decreases with blue HB stars on the metal-poor side ([Fe/H] < −1.0) by 0.2 Å at 14 Gyr. The bottom left panel of Figure 9 depicts that Fe5270 increases in general with a bottom-heavy IMF, particularly on the metal-rich side ([Fe/H] ≥ −1.0). The bottom right panel shows that the effect from blue HBs becomes commensurately important with top-heavy IMF on the metal-poor side ([Fe/H] < −1.0).

Although the $\alpha$-element enhancement effects on Fe5335 shown in the top left panel of Figure 10 is similar to that on Fe5270 in the top left panel of Figure 9, it is noted from the middle right panel of Figure 10 that the spectral effects do not make Fe5335 stronger on the metal-poor side as they do for Fe5270. According to Table 1, it is mostly Mg-enhancement which weakens Fe5335; Ca-enhancement does not influence Fe5335 significantly as it does Fe5270. The top right panel of Figure 10 displays that the HB effect is similar, though in less degree, to Fe5270. Fe5335 diminishes by 0.15 Å with blue HB stars at 14 Gyr. The

---

*It becomes clear in Lee et al. (2009) that Fe4531 and Fe5015 are Ti-sensitive indices.*
bottom panels illustrate that the IMF effect is similar to Fe5270.

The top left panel of Figure 11 depicts that the \( \alpha \)-element enhancement effects on Fe5406 is relatively minor compared to that on Fe5270 and Fe5335 on the metal-poor side ([Fe/H] \( \leq \) −1.0). From the middle panels of Figure 11, we find that it is the spectral effects that cancel out the isochrone effects on the metal-poor side. According to Table 1, all the \( \alpha \) elements make Fe5406 weaker, though the primary element is Mg. Similar to Fe5270 and Fe5335, the top right panel of Figure 11 illustrates that the blue HB stars on the metal-poor side make Fe5406 weaker by \( \sim 0.1 \) Å at 14 Gyr. The bottom panels display that the IMF effect is similar to Fe5270 and Fe5335.

The top left panel of Figure 12 shows that the \( \alpha \)-enhancement on Fe4383 is similar to that on Fe5406 rather than Fe5270 and Fe5335. It is noted from the middle right panel of Figure 12 that the spectral effects due to \( \alpha \)-element enhancement grow systematically stronger with increasing metallicity. According to Table 1, all the \( \alpha \) elements except Ti make Fe4383 weaker, the leading element is Mg. Similar to Fe5270, Fe5335, and Fe5406, the top right panel of Figure 12 displays that the blue HB stars on the metal-poor side make Fe5406 weaker by 0.6 Å at 14 Gyr. The bottom panels illustrate that the IMF effect is similar to Fe5270, Fe5335, and Fe5406.

4. Comparisons with Milky Way Globular Clusters

Having discussed the theoretical outputs of our SSP model \( \alpha \)-enhanced Lick spectral indices in § 3, we now provide empirical checks of our models using the Milky Way GCs. In this work, we use recent the large, homogeneous dataset of 41 integrated spectra of the Milky Way GCs by S05. There are 40 MWGCs listed in Table 1 of S05 and we find that NGC 7078 is also available from their spectra, hence the total sample has 41 GCs, some with multiple observations. We have averaged the measured Lick index values when there are multiple observations. Figures 13 − 16 display [Fe/H] vs. Lick index plots in order to take advantage of independent measurements of [Fe/H] and [\( \alpha \)/Fe] from individual stars in the Milky Way GCs. The [Fe/H] values were taken from Table 1 of S05. Our simple stellar population models with realistic HB morphologies are shown for several Lick indices as a function of [Fe/H]. The blue lines are solar-scaled models with HB stars (ss-wHB), while the pink lines are +0.4 dex \( \alpha \)-enhanced models (aa-wHB; both isochrones and spectra are enhanced). Ages of our models are noted next to the \( \alpha \)-enhanced models: filled circles are for

\footnote{We use [Fe/H] = −2.45 for NGC 7078 following the Table 7 of Kraft & Ivans (2003) based on MARCS models as we describe in section 4.3.}
8 Gyr, open squares are for 11 Gyr, and filled squares are for 14 Gyr, respectively. The SSP models were computed at \([\text{Fe/H}] = -2.5, -2.0, -1.5, -1.0, -0.5, \text{and } 0.0\) and are connected by straight lines in the figures.

We describe how our SSP model Lick indices of Mg\(b\) and Ca4227, Balmer lines, and Fe lines are compare with observations of Milky Way GCs in sections 4.1, 4.2, and 4.3, respectively. Comparisons of our model metal line indices with Milky Way GCs are of great importance. This is because age estimation using the diagnostic diagram of a metal line index vs. a Balmer line index could be misleading unless the calibrations of model metal line indices are carefully considered. We remind readers again, however, that the purpose of this study is not investigating the detailed match between models and the observations for every individual GC, but rather to look into the overall match for the entire range of \([\text{Fe/H}]\) because of the caveats (i.e., no blue stragglers, binaries, multiple populations, CNONa considerations, etc) of our models as delineated in section 2.

4.1. Mg\(b\) and Ca4227

From the left panel of Figure 13, it is seen that the overall match between MWGCs and our 0.4 dex \(\alpha\)-enhanced SSP models is good. Although it seems that the metal-poor GCs \(([\text{Fe/H}] < -1.0)\) indicate \([\alpha/\text{Fe}] \sim 0.2 - 0.3\) dex, it is again not an aim of this study to investigate the every individual Milky Way GC’s location on our model grids. There is mounting evidence that not every \(\alpha\)-element is equally enhanced in MWGCs and not every MWGC is of the similar amount of \(\alpha\)-element enhancement (e.g., Gratton, Sneden, & Carretta 2004; Pritzl, Venn, & Irwin 2005). Our models represent the case when all the \(\alpha\) elements are equally enhanced by 0.4 dex. Lee et al. (2009) have noted that Mg\(b\) is primarily sensitive to Mg alone and other elements do not much affect it so that \([\alpha/\text{Fe}] = 0.4\) dex should be equivalent to \([\text{Mg/Fe}] = 0.4\) for Mg\(b\).

From the right panel of Figure 13, it is indicated that \([\alpha/\text{Fe}] ([\text{Ca/Fe}]) \sim +0.2\) would reproduce the observations better. As Pritzl et al. (2005) showed, it may be true that Ca is less enhanced compared to Mg in the stars of MWGCs. Pipino et al. (2009) recently suggest that the observed under-abundance of Ca with respect to Mg could be attributed to the different contributions from supernovae Type Ia and supernovae Type II to the nucleosynthesis of these two elements. The two most metal-rich Milky Way GCs in Figure 13 are NGC 6553 ([Fe/H] = −0.20) and NGC 6528 ([Fe/H] = −0.10). It seems that both of them indicate a lower amount of \(\alpha\)-enhancement compared to their metal-poor counterparts. For NGC 6553, Cohen et al. (1999) and Alves-Brito et al. (2006) report \([\text{Ca/Fe}] = +0.06\) and +0.05, respectively. For NGC 6528, Carretta et al. (2001) and Zoccali et al. (2004) report
[Mg/Fe] = −0.04 and −0.06, respectively.

4.2. Balmer Line Indices

Balmer lines are widely used as an age indicator because of their superb temperature sensitivity in stars, tracing the temperature of the main-sequence turnoff better than many other indices. However, Lee et al. (2009) and earlier works (Worthey et al. 1994; Thomas et al. 2004; Lee & Worthey 2005; Coelho et al. 2007; Schiavon 2007) found that they are also abundance sensitive to some degree. The horizontal-branch effect on Hβ was also investigated by Lee et al. (2000).

Figures 14 and 15 are similar to Figures 1 and 2 of Lee & Worthey (2005), but here we see the combination of isochrone and spectral effects of 0.4 dex α-element (O, Mg, Si, S, Ca, Ti) enhancement after the correction of the stellar library’s intrinsic abundance patterns. From the top right panels of Figures 4 – 8, we have learned that blue HB stars significantly affect the Balmer lines (Hβ, Hγ, Hδ) for the old stellar populations on the metal-poor side. It is clear from Figures 14 and 15 that the HB effect indeed improves the agreement between our models and observations. It is useful to note here that most Milky Way GCs have ages between ~11-14 Gyr (e.g., Salaris & Weiss 2002).

Figure 14 shows that the overall match is rather good although that the observations are a little bit weaker than the models, particularly those for −1.0 < [Fe/H] < −0.6. We can see Poole et al. (2009) for a more detailed discussion, but a few words about outliers might be useful. The biggest outlier is NGC 6544 ([Fe/H] = −1.38; red open circle) in Figure 14, that shows significantly weaker Hβ compared to other MWGCs with similar metallicity (although only much slightly weaker at Hγ and Hδ in Figure 15). According to Harris (1996; 2003 updated version) MWGC compilation, NGC 6544 has considerably large reddening than other GCs in the S05 sample, E(B−V) = 0.73. Moreover, Figure 1 of Hazen (1993) shows that there is a rather bright foreground star within 2′ from the center of NGC 6544. Several MWGCs with −1.0 < [Fe/H] < −0.6 also show some mismatches against models. Among the other clusters in the sample, it is interesting to find that NGC 6388 ([Fe/H] = −0.68; red open circle) and NGC 6441 ([Fe/H] = −0.65; red open circle), which have unusually sizable population of blue HB stars for their metallicities (Rich et al. 1997), have stronger Hβ features than 47 Tuc (([Fe/H] = −0.70; red open circle), which has a purely red HB. However, high reddening is not a compelling method to weaken Hβ even if it were physically motivated because 47 Tuc, with very low reddening E(B−V) = 0.04 (Harris 1996), has weaker Hβ compared to NGC 6388 and NGC 6441 with significantly high reddening (E(B−V) = 0.37 and 0.47, respectively).
For NGC 6553 ([Fe/H] = −0.20), a significant population of blue stragglers is seen in Beaulieu et al. (2001) and Zoccali et al. (2001) and for NGC 6528 ([Fe/H] = −0.10) similarly notable population of blue stragglers are seen in Brown et al. (2005). They may explain rather strong Hβ from NGC 6553 and NGC 6528 compared to those Hβ-weak MWGCs with −1.0 < [Fe/H] < −0.6.

The top right panel of Figure 4 (HB effects) showed that blue HB stars on the metal-poor side ([Fe/H] < −1.0) for the old stellar populations (t > 8 Gyr) make Hβ stronger as much as 0.7 Å. The middle left panel of Figure 4 (isochrone effects) on the other hand depicted that α-enhanced isochrones at fixed [Fe/H] make Hβ weaker by up to 0.3 Å relative to scaled-solar for old stellar populations (t ≥ 8 Gyr). The middle right panel of Figure 4 displayed that the α-enhanced synthetic spectra are not doing much at all. The α-enhanced spectra are important only near solar metallicity. It is mostly the cooler, α-enhanced isochrones that are important for Hβ. Perhaps, α-enhanced isochrones are required to match the observations at realistic ages, though an even stronger effect than what we find would be required. Alternatively, a modest emission-line fill-in in the indices is needed to bring the models into agreement with the data [Poole et al. 2009].

The overall agreement between the α-enhanced SSP models of Hγ and Hδ Lick indices and the MWGCs in Figure 15 are much better than what we found for Hβ, as shown in Figure 14. However, it is the case that the α-enhanced models differ less from the scaled-solar models for Hγ and Hδ than they did for Hβ. NGC 6544 ([Fe/H] = −1.38; red open circle) is still an outlier but not to the great extent that it is for Hβ. As with Hβ, NGC 6388 and NGC 6441, with sizable population of blue HB stars, show relatively stronger Hγ and Hδ within a small metallicity range (again, these two and 47 Tuc are marked with red open circles for comparison), particularly at Hγ.

The top and middle panels of Figures 5 – 8 illuminated that the isochrone and spectral effects of α-element enhancement on Hγ and Hδ go in the opposite direction and their effects are cancelled out on the metal-poor side, exposing mostly the HB effect alone. Among four Hγ and Hδ indices, HγA has the broadest dynamic range (∼8 Å difference between NGC 7078 with [Fe/H] = −2.45 and NGC 6528 with [Fe/H] = −0.10). The bottom panels of Figure 15 display that HγF and HδF are very similar to HγA and HδA in the upper panels, except for a narrower dynamic range.
4.3. Iron Line Indices

In Figure 16, we see that the overall match between Lick iron indices and the MWGCs is generally good although not superb in Fe5270 particularly around [Fe/H] \( \sim -1.0 \). One of the culprits, is perhaps, the spectral effect of Ca as we described in section 3.3. Isochrone effects from individual element need to be investigated because \( \alpha \)-enhanced isochrone effects become significant near [Fe/H] = -1.0. Dotter et al. (2007a) investigated individual elemental effects on the isochrones only at the solar metalicity. The dynamic range of Fe5406, which is claimed to be the least sensitive to every element except iron among Lick iron indices (Lee et al. 2009; Percival et al. 2009), is only slightly smaller (\( \sim 1.6 \) \( \AA \)) compared to that of Fe5270 (\( \sim 2.4 \) \( \AA \)) and Fe5335 (\( \sim 2.0 \) \( \AA \)).

Despite the use of high-resolution spectra of individual stars, the discrepancy of [Fe/H] estimation can be quite large among different studies even though their internal uncertainties are often fairly small. For example, Barbuy et al. (1999) found NGC 6553 to have [Fe/H] = -0.55 while Carretta et al. (2001) found [Fe/H]= -0.06. To demonstrate the effect of changing the [Fe/H] scale we present Figure 17, which is the same as Figure 16, but the [Fe/H] values of MWGCs are from Harris (1996) compilation instead of Table 1 of S05. Compared to Figure 16, the matches are not very favorable especially at \(-1.0 < \text{[Fe/H]} < -0.5\).

In Figure 18, we compare [Fe/H] values in Table 1 of S05 with several different [Fe/H] compilations available in the literature. They are Harris (1996; 2003 version), Zinn & West (1984), Carretta & Gratton (1997), and Kraft & Ivans (2003). The top left panel of Figure 18 compares [Fe/H] values in Table 1 of S05 with Harris 2003 compilation. 40 MWGCs except NGC 7078 are displayed here. The middle left panel shows the comparison between S05 and Zinn & West (ZW84) [Fe/H] in Table 7 of Kraft & Ivans (2003). 29 MWGCs are shown here. By comparing these two, we notice that the Harris 2003 compilation generally follows the ZW84 [Fe/H]. We illustrated in Figure 17 that our SSP models do not go very well along with [Fe/H] of Harris 2003 compilation.

The top right panel of Figure 18 compares [Fe/H] values of S05 with that of Carretta & Gratton (CG97)\(^6\) estimated by Rutledge, Hesser, & Stetson (1997). 30 MWGCs are shown

\(^5\)We use his 2003 version, \url{http://physwww.mcmaster.ca/~harris/mwgc.dat}

\(^6\)They are listed in Table 2 of Rutledge, Hesser, & Stetson (1997).
It seems that there are about 0.18 dex systematic differences between them. From the comparison between middle right panel (Kraft & Ivans 2003 [Fe/H] estimation based upon MARCS models) and bottoms panels (left: Kraft & Ivans 2003 [Fe/H] estimation based upon Kurucz models with convective overshooting, right: that without convective overshooting) of Figure 18, it seems that the [Fe/H] values in Table 1 of S05 correlate very well with [Fe/H] in Table 7 of Kraft & Ivans (2003) based on MARCS models.

5. Summary and Conclusions

We have presented scaled-solar and α-enhanced SSP models as for several Lick/IDS indices using the Dotter et al. (2007b) stellar evolution models combined with high resolution synthetic spectra. Realistic HB morphologies are incorporated in order to represent the Milky Way GCs. Furthermore, we have investigated the effect of IMF variation on the Lick indices. It is realized that, among the α elements, Mg significantly influences the spectral effects on Balmer and iron line indices. From the comparison of our models of Mg $b$ and Ca4227 with the Schiavon et al. (2005) dataset (Figure 13), we can confirm an enhancement of about 0.4 dex for Mg and about 0.2 dex for Ca, in agreement with the measured amounts from the high resolution spectra of individual stars in MWGCs (Pritzl, Venn, & Irwin 2005). Moreover, we note that our SSP model Lick iron indices comply with the Kraft & Ivans (2003) [Fe/H] based upon MARCS models. Balmer lines, particularly Hγ and Hδ of MWGCs, are also well reproduced by our α-enhanced models not only because of the combination of isochrone and spectral effects but also because of our realistic HB treatment. Finally, the investigation of IMF variations on Lick indices reveals that a giant-dominant IMF can be ruled out because the Balmer lines are too strong on the metal-poor side to be compatible with observations.

Support for this work was provided by the NASA through grant HST-GO-11083.

---

7NGC 6553 is additionally listed in Table 2 of Rutledge et al. (1997) compared to Table 7 of Kraft & Ivans (2003).

8This is noted in footnote ‘d’ in Table 1 of S05. In the literature, we note that the very recent [Fe/H] estimation of NGC 6388 by Carretta et al. (2007) is −0.44 and that of NGC 6441 by Gratton et al. (2007) is −0.34 compared to −0.68 and −0.65, respectively from Table 1 of S05.

[Fe/H] = 0.0

Note. — 1. The units are Å of equivalent width. 2. The second column is the index of solar-scaled models without HB stars. 3. ∆I = index of each element-enhanced by 0.4 dex at fixed [Fe/H] = index of solar-scaled model, both without HB stars. 4. α in the last column is the case that all of O, Mg, Si, S, Ca, and Ti are enhanced by 0.4 dex at fixed [Fe/H] without HB stars.
Fig. 1.— H-R diagram comparisons are illustrated between solar-scaled and 0.4 dex α-element enhanced isochrones at 8, 11, and 14 Gyr. The left panel shows them at [Fe/H] = −2.0, while the right panel displays them at [Fe/H] = 0.0. The horizontal-branch (HB) morphologies are only shown for 11 Gyr. The small squares are HB stars for the solar-scaled, while the crosses are that for the α-enhanced. The α-enhanced isochrones and HB stars here at fixed [Fe/H] are generally cooler than that of the solar-scaled. Moreover, it is noted that the α-element enhancement effects are more significant on the metal-rich side.
Fig. 2.— The residuals of our simple stellar population (SSP) models for Mg $b$ are illuminated. In the top left panel, the differences between 0.4 dex $\alpha$-enhanced models (both isochrones and spectra are enhanced) without HB stars and that of the solar-scaled (aa-woHB – ss-woHB) are displayed. Ages of our SSP models are denoted as filled circles for 8 Gyr, open squares for 11 Gyr, and filled squares for 14 Gyr, respectively. Metallicities of our SSP models are given at $[\text{Fe/H}] = -2.5, -2.0, -1.5, -1.0, -0.5,$ and 0.0. The top right panel shows the effect of HB stars at the $\alpha$-enhanced models (aa-wHB – aa-woHB). The middle panels are same as the top left panel, but the middle left panel displays isochrone effects alone without HB stars (as-woHB – ss-woHB), while the middle right panel depicts spectral effects alone without HB stars (sa-woHB – ss-woHB). The combination of the middle panels corresponds to the top left panel. It is demonstrated in the middle panels that both the $\alpha$-enhanced isochrones and spectra make Mg $b$ stronger as a function of $[\text{Fe/H}]$, but the latter are dominant. The top panels show that HB stars do not influence Mg $b$ much compared to $\alpha$-element enhancement. The bottom panels depict the variation of IMF effect, 3.35 for dwarf-dominant, 1.35 for giant-dominant, without (left) and with HB stars (right) at 11 Gyr for our 0.4 dex $\alpha$-enhanced SSP models (see section 2.3 for details). It is seen from the bottom panels that the dwarf-dominant IMF generally makes Mg $b$ stronger.
Fig. 3.— Same as Figure 2, but for Ca4227. The top left panel illustrates the combination of the middle panels. Similar to Mg b, it is shown in the middle panels that both the $\alpha$-enhanced isochrones and spectra make Ca4227 stronger as a function of [Fe/H], but the latter are dominant. Similar to Mg b, the top panels display that HB stars do not affect Ca4227 much compared to $\alpha$-element. The bottom panels show that the dwarf-dominant IMF generally makes Ca4227 stronger except at the solar metallicity.
Fig. 4.— Same as Figure 2, but for Hβ. The top left panel illustrates the combination of the middle panels. It is seen from the top right panel that Hβ increases as much as 0.7 Å on the metal-poor side for old stellar populations due to blue HB stars. Also, it is noted from the middle panels that the α-element enhancement effects are mostly due to the cooler isochrones, which decrease the temperature sensitive Hβ, while the spectral effects are almost negligible except at the solar metallicity. The bottom panels show that the giant-dominant IMF generally makes Hβ stronger on the metal-poor side and the vice versa, which is attributed to the temperature sensitivity of Hβ.
Fig. 5.— Same as Figure 2, but for HγA. The top left panel illustrates the combination of the middle panels. Similar to Hβ, the top right panel shows that HγA increases as much as 2.4 Å on the metal-poor side for old stellar populations due to blue HB stars. Also, it is noted from the middle panels that the isochrone and spectral effects due to α-element are opposite (see text for details). The bottom right panel shows that the giant-dominant IMF makes HγA considerably stronger on the metal-poor side mostly because of the blue HB stars.
Fig. 6.— Same as Figure 2, but for $H\gamma_F$. The top left panel illustrates the combination of the middle panels. Similar to $H\gamma_A$, the top right panel shows that $H\gamma_F$ increases as much as 1.4 Å on the metal-poor side for old stellar populations due to blue HB stars. Also, it is noted from the middle panels that the isochrone and spectral effects due to $\alpha$-element are opposite. The bottom right panel shows that the giant-dominant IMF makes $H\gamma_F$ considerably stronger on the metal-poor side mostly because of the blue HB stars.
Fig. 7.— Same as Figure 2, but for Hδ_A. The top left panel illustrates the combination of the middle panels. Similar to Hγ_A, the top right panel shows that Hδ_A increases as much as 1.8 Å on the metal-poor side for old stellar populations due to blue HB stars. Also, it is noted from the middle panels that the isochrone and spectral effects due to α-element are opposite (see text for details). The bottom right panel shows that the giant-dominant IMF makes Hδ_A considerably stronger on the metal-poor side mostly because of the blue HB stars.
Fig. 8.— Same as Figure 2, but for H$\delta_F$. The top left panel illustrates the combination of the middle panels. Similar to H$\delta_A$, the top right panel shows that H$\delta_F$ increases as much as 1.2 Å on the metal-poor side for old stellar populations due to blue HB stars. Also, it is noted from the middle panels that the isochrone and spectral effects due to $\alpha$-element are opposite. The bottom right panel shows that the giant-dominant IMF makes H$\delta_F$ considerably stronger on the metal-poor side mostly because of the blue HB stars. The bottom left panel shows that the IMF effect on H$\delta_F$ is minimal among Balmer lines unless we consider HB stars.
Fig. 9.— Same as Figure 2, but for Fe5270. The top left panel illustrates the combination of the middle panels. The top right panel shows that Fe5270 decreases with blue HB stars on the metal-poor side. The middle panels display that both isochrone and spectral effects due to $\alpha$-element make Fe5270 stronger on the metal-poor side, but the spectral effects near solar metallicity make it weaker (see text for details). The bottom panels show that the dwarf-dominant IMF makes Fe5270 stronger.
Fig. 10.— Same as Figure 2, but for Fe5335. The top left panel illustrates the combination of the middle panels. Similar to Fe5270, but in less degree, the top right panel shows that Fe5335 decreases with blue HB stars on the metal-poor side. It is noted from the middle panels that the isochrone and spectral effects due to $\alpha$-element are opposite (see text for details). The bottom panels show that the dwarf-dominant IMF makes Fe5335 stronger.
Fig. 11.— Same as Figure 2, but for Fe5406. The top left panel illustrates the combination of the middle panels. Similar to Fe5270 and Fe5335, the top right panel shows that HB effect on Fe5406 decreases with blue HB stars on the metal-poor side. Compared to Fe5270 and Fe5335, it is noted from the middle right panel that the spectral effects due to α-element make Fe5406 weaker even at the metal-poor side, [Fe/H] < −1.0 (see text for details). The bottom panels show that the dwarf-dominant IMF makes Fe5406 stronger.
Fig. 12.— Same as Figure 2, but for Fe4383. The top left panel illustrates the combination of the middle panels. Similar to Fe5270, the top right panel shows that Fe4383 decreases with blue HB stars on the metal-poor side. It is noted from the middle right panel that the spectral effects due to $\alpha$-element are systematically stronger with increasing metallicity (see text for details). The bottom panels show that the dwarf-dominant IMF makes Fe4383 stronger.
Fig. 13.— Our simple stellar population models (SSP) with realistic horizontal-branch (HB) morphologies are shown for Mg $b$ (left) and Ca4227 (right) as a function of [Fe/H]. The blue lines are our solar-scaled SSP models with HB stars (ss-wHB), while the pink lines are that of 0.4 dex $\alpha$-enhanced (aa-wHB; both isochrones and spectra are enhanced). Ages of our models are denoted next to the $\alpha$-enhanced models in right panel. Metallicities of our models are given at [Fe/H] = −2.5, −2.0, −1.5, −1.0, −0.5, and 0.0. The diamonds are 41 Milky Way globular clusters (MWGCs) from Schiavon et al. (2005; S05). The [Fe/H] of MWGCs are also from Table 1 of S05. Because Mg $b$ and Ca4227 are predominantly sensitive to Mg and Ca, respectively, among $\alpha$ elements, it is denoted here that the MWGCs are, in general, of $[\text{Mg/Fe}] \sim 0.4$ dex and $[\text{Ca/Fe}] \sim 0.2$ dex. The two most metal-rich MWGCs in the sample, NGC 6553 ([Fe/H] = −0.20) and NGC 6528 ([Fe/H] = −0.10), however, seem to indicate the less amount of enhancement of $\alpha$-element compared to the metal-poor counterparts (see text for details).
Fig. 14.— $H\beta$ as a function of [Fe/H], with lines a symbols as in Figure 13, except for some clusters marked with circles. These are NGC 6544 ([Fe/H] = −1.38), which is considerably weaker in $H\beta$ compared to other MWGCs with similar metallicity, NGC 6388 ([Fe/H] = −0.68) and NGC 6441 ([Fe/H] = −0.65) are of the strongest $H\beta$ with sizable numbers of blue HB stars compared to 47 Tuc ([Fe/H] = −0.70) that has a pure red clump (see text for details).
Fig. 15.— Similar to Figure 14, but for $H\gamma_A$ (upper left), $H\delta_A$ (upper right), $H\gamma_F$ (lower left), and $H\delta_F$ (lower right). It seems that the matches between our $\alpha$-enhanced SSP models and the MWGCs in $H\gamma$ and $H\delta$ are, in general, much better than that in $H\beta$ as shown in Figure 14. Unlike $H\beta$, NGC 6544 ([Fe/H] = −1.38; red open circle) does not significantly stand out. Similar to $H\beta$, NGC 6388 ([Fe/H] = −0.68; red open circle) and NGC 6441 ([Fe/H] = −0.65; red open circle) are of the stronger $H\gamma$ and $H\delta$ with sizable blue HB stars compared to 47 Tuc ([Fe/H] = −0.70; red open circle) which a strong red clump with basically zero bluer HB stars (see text for details).
Fig. 16.— Similar to Figure 13, but for Fe5270 (upper left), Fe5335 (upper right), Fe5406 (lower left), and Fe4383 (lower right). It appears that the matches between our SSP models and the MWGCs in Lick iron indices are generally good, particularly in Fe5406 and Fe4383 (see text for details).
Fig. 17.— Same as Figure 16, but the [Fe/H] values of MWGCs are from Harris 2003 compilation instead of Table 1 of Schiavon et al. (2005). Compared to Figure 16, the matches are not very favorable, especially at $-1.0 < [\text{Fe/H}] < -0.5$. 
Fig. 18.— Several different cluster [Fe/H] compilations from the literature are compared with that of Table 1, Schiavon et al. (2005). They are the Harris 2003 compilation (top left), Carretta & Gratton (CG97) in Table 2 of Rutledge, Hesser, & Stetson (1997) (top right), and Zinn & West (ZW84) (middle left), MARCS (middle right), Kurucz-on (bottom left), Kurucz-off (bottom right) in Table 7 of Kraft & Ivans (2003), respectively (see text for details).
